

## AS 91390: Demonstrate understanding of thermochemical principles and the properties of particles and substances

### *Explaining why atomic radii decrease (get smaller) going across a period*

Across a period, the effective nuclear charge increases.

Both have the

- same number of electron shells
- same energy levels
- same shielding of outer e's by inner e's
- same repulsion from inner shell electrons
- valence e's in same energy level

but \_\_\_ has a greater

- nuclear charge
- no of protons

so there is a stronger attraction for the valence electrons, bringing them in closer, resulting in a smaller radius.

Example: Cl < Na

### *Explaining why cations are smaller than the parent atoms they were formed from*

\_\_\_\_\_ is smaller than \_\_\_\_\_ because it has lost an electron(s) from an entire valence shell so the electrons are

- only in \_\_\_\_\_ shells / energy levels instead of \_\_\_\_\_ shells / energy levels
- in less shells / energy levels

Example: Na<sup>+</sup> < Na

### *Explaining why anions are larger than the parent atoms they were formed from*

\_\_\_\_\_ is larger than \_\_\_\_\_ because it has gained electron(s) leading to increased electron-electron repulsion increasing the size of the electron cloud so \_\_\_ > \_\_\_

Example: Cl<sup>-</sup> > Cl

### *Explaining why atomic radii increase (get bigger) going down a group*

\_\_\_\_\_ is larger than \_\_\_\_\_ because the added electron(s) go into a whole new valence shell & shielding is greater / repulsion from inner shells has increased (so bonding electrons will be further from the positive nucleus) so there is weaker (electrostatic) attraction between the nucleus and the valence electrons.

Example: K > Na

**Explaining why molecules and ions have a particular shape**

There are 

2	<ul style="list-style-type: none"> <li>• regions of electron density</li> <li>• regions of negative charge*</li> </ul>
3	
4	
5	
6	
6	

 around the central atom which **repel** to take a 

<ul style="list-style-type: none"> <li>• linear</li> <li>• trigonal planar</li> <li>• tetrahedral</li> <li>• trigonal bipyramidal</li> <li>• octahedral</li> </ul>
--

 arrangement 

<ul style="list-style-type: none"> <li>• to minimise repulsion</li> <li>• to get as far apart as possible</li> </ul>
--

\* single / double / triple bond / lone pair = one region of negative charge

There are \_\_\_ bonding electron pairs **and** \_\_\_ lone pairs which results in a 

<ul style="list-style-type: none"> <li>• linear</li> <li>• v-shaped</li> <li>• trigonal planar</li> <li>• trigonal pyramidal</li> <li>• tetrahedral</li> <li>• trigonal bipyramidal</li> <li>• see-saw / distorted tetrahedron</li> <li>• t-</li> <li>• octahedral</li> <li>• square pyramidal</li> <li>• square planar</li> </ul>
--

 shape 

<ul style="list-style-type: none"> <li>• molecule</li> <li>• ion</li> </ul>
---

**Explaining why a covalent molecule is polar or non-polar**

The \_\_\_-\_\_\_ bond(s) is/are 

<ul style="list-style-type: none"> <li>• polar</li> <li>• non polar</li> </ul>
--

 because of EN difference\*\* & molecule is 

<ul style="list-style-type: none"> <li>• symmetrical</li> <li>• asymmetrical</li> </ul>
---

 so 

<ul style="list-style-type: none"> <li>• the bond dipoles cancel out / don't cancel out</li> <li>• centre of +ve and -ve charge coincide / don't coincide</li> </ul>
--

 & so the molecule is 

<ul style="list-style-type: none"> <li>• polar</li> <li>• non-polar</li> </ul>
--

\*\* (state \_\_\_ is more electronegative than \_\_\_ OR draw the  $\delta^+$  and  $\delta^-$  above a bond OR use  $\rightarrow$  to indicate, if you can )

**Explaining why first ionisation energy increases across a period but decreases down a group**

\_\_\_ and \_\_\_ have the same number of shells but \_\_\_ has 

<ul style="list-style-type: none"><li>• greater nuclear charge</li><li>• greater number of protons</li></ul>
--

 so greater electrostatic attraction between nucleus and valence electrons

\_\_\_ has the greatest number of electron shells, so its electrons are further from the nucleus, so less energy is required to remove a valence electron. It also has greater shielding effect of an additional shell between the valence shell and the nucleus / repulsion from inner shell electrons increases and so less energy is required to remove the outermost electron.

E.g. Ca < Mg < Cl

**Explaining why electronegativity increases across a period but decreases down a group**

Valence electrons are 

<ul style="list-style-type: none"><li>• added to same shell</li><li>• the same distance from nucleus</li></ul>
--

 but in \_\_\_ there is a greater 

<ul style="list-style-type: none"><li>• number of protons</li><li>• nuclear attraction</li></ul>
--

 so val. electron(s) is/are more strongly attracted

But going down a group nuclear charge increases but so does shielding too, so the atomic radii increase causing less attraction of electrons to the nucleus.

E.g. why F > O > N and why Cl < F

Extension: **No longer examined @ L3**

**Explaining why TM can form compounds with variable oxidation states / can form a range of oxides and a group 1 or 2 metal like Ca cannot**

\_\_\_ only has \_\_\_ valence electron(s) which it loses to form a \_\_\_ + ion but \_\_\_ has valence electrons in 3d & 4s which it can lose to form stable ions or share covalently

E.g. Ca and Mn
